

# Package ‘PSweight’

October 28, 2021

**Type** Package

**Title** Propensity Score Weighting for Causal Inference with  
Observational Studies and Randomized Trials

**Version** 1.1.5

**Date** 2021-10-27

**Maintainer** Tianhui Zhou <tianhui.zhou@duke.edu>

**Description** Supports propensity score weighting analysis of observational studies and randomized trials. Enables the estimation and inference of average causal effects with binary and multiple treatments using overlap weights (ATO), inverse probability of treatment weights (ATE), average treatment effect among the treated weights (ATT), matching weights (ATM) and entropy weights (ATEN), with and without propensity score trimming. These weights are members of the family of balancing weights introduced in Li, Morgan and Zaslavsky (2018) <[doi:10.1080/01621459.2016.1260466](https://doi.org/10.1080/01621459.2016.1260466)> and Li and Li (2019) <[doi:10.1214/19-AOAS1282](https://doi.org/10.1214/19-AOAS1282)>.

**Depends** R (>= 3.5.0)

**License** GPL (>= 2)

**URL** <https://github.com/thuizhou/PSweight>

**Encoding** UTF-8

**LazyData** true

**RoxygenNote** 7.1.1

**Suggests** knitr, rmarkdown

**Imports** nnet, MASS, ggplot2, numDeriv, gbm, SuperLearner

**NeedsCompilation** no

coef.PSweight	<i>Point estimates of PSweight</i>
---------------	------------------------------------

---

**Description**

The `coef` method for class "PSweight"

**Usage**

```
## S3 method for class 'PSweight'
coef(object, ...)
```

**Arguments**

object	an object for which the extraction of model coefficients is meaningful.
...	other arguments.

**Value**

The output from `coef`

---

NCDS

*Illustrative dataset for PSweight*

---

### **Description**

This is a real observational study with binary and multiple treatment groups to illustrate the utility of PSweight functions.

### **Usage**

```
data(NCDS)
```

### **Format**

A data frame with 3642 rows and 16 columns.

### **Details**

An dataset from the National Child Development Survey (NCDS) of the United Kingdom (UK). This dataset is obtained through the CC0 waiver from the work by Battistin and Sianesi (2011). For illustration, missing entries are imputed once with Multiple Imputation by Chained Equations (MICE).

This data frame contains the following columns:

- white: self-identified as white.
- wage: gross hourly wage in pound in log scale.
- Dany: whether received any education before.
- Dmult: three levels of educational attainment.
- maemp: employment status of mother.
- scht: school type.
- qmab: math score at age 7.
- qmab2: math score at age 11.
- qvab: reading score at age 7.
- qvab2: reading score at age 11.
- paed\_u: father's years of education.
- maed\_u: mother's years of education.
- age\_pa: age of father.
- age\_ma: age of mother.
- sub\_u: number of siblings.
- wagebin: dichotomized wage obtained with a cutoff of average hourly wage.

## Examples

```
data("NCDS")
```

---

OUTmethod

*Fitting potential outcome regression with different methods*

---

## Description

The function `OUTmethod` is an internal function to estimate the potential outcomes given a specified model through formula. It is built into function `PSweight`, and is used for constructing the augmented estimators.

## Usage

```
OUTmethod(
  out.formula = out.formula,
  y = y,
  out.method = "glm",
  family = "gaussian",
  datain = datain,
  dataout = dataout,
  ...
)
```

## Arguments

<code>out.formula</code>	an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the outcome model to be fitted.
<code>y</code>	a vector of the observed outcome in the training data ( <code>datain</code> ).
<code>out.method</code>	a character to specify the method for estimating the outcome regression model. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
<code>family</code>	a description of the error distribution and link function to be used in the outcome model. Supported distributional families include "gaussian" (link = identity), "binomial" (link = logit) and "poisson" (link = log). Default is "gaussian".
<code>datain</code>	The training data for the outcome model. In the context of <code>PSweight</code> , it refers to the data observed for each treatment group.

dataout	The prediction data for the outcome model. In the context of PSweight, it refers to the full data.
...	further arguments passed to or from other methods.

### Details

A typical form for `out.formula` is  $y \sim \text{terms}$  where  $y$  is the outcome variable and `terms` is a series of terms which specifies linear predictors (on the link function scale). `out.formula` by default specifies generalized linear model given the gaussian error through the default arguments `method = "glm"` and `family = "gaussian"`. It fits the logistic regression when `family = "binomial"`, and poisson regression when `family = "poisson"`. The argument `out.method` allows user to choose model other than glm to fit the outcome regression models for constructing the augmented estimator. We have included `gbm` and `SuperLearner` as alternative machine learning estimators. Additional argument in them can be supplied through the `...` argument. Please refer to the user manual of the `gbm` and `SuperLearner` packages for all the allowed arguments.

### Value

`m.est` a vector of predicted outcome on the `dataout`.  
`gamma.h` estimated coefficient of the outcome model when `method = "glm"`.

### Examples

```
#' the outcome model
out.formula <- Y~cov1+cov2+cov3+cov4+cov5+cov6
y <- psdata$Y
#train on model with treatment group 1
datain <- psdata[psdata$trt==1, ]
outfit <- OUTmethod(out.formula = out.formula, y=y, datain = datain, dataout = psdata)
```

---

plot.SumStat

*Plot the distribution of propensity scores and balance statistics*

---

### Description

Summarize the `SumStat` object, generate histogram or density of estimated propensity scores and plot the balance statistics under weighting versus no weighting.

### Usage

```
## S3 method for class 'SumStat'
plot(
  x,
  type = "balance",
  weighted.var = TRUE,
  threshold = 0.1,
```

```

    metric = "ASD",
    breaks = 50,
    ...
  )

```

### Arguments

x	a SumStat object obtained with <a href="#">SumStat</a> function.
type	a character indicating the type of plot to produce, including histogram of estimated propensity scores ("hist"), density of estimated propensity scores ("density"), and plot of balance statistics ("balance").
weighted.var	logical. Indicating whether weighted variance should be used in calculating the balance statistics. Default is TRUE.
threshold	an optional numeric value indicating the balance threshold for the balance plot. Default is 0.1. Only valid when type = "balance".
metric	a character indicating the type of metric used in balance plot. Only "ASD" or "PSD" is allowed. If not specified, the default is "ASD". See <a href="#">summary.SumStat</a> for additional details on balance metrics.
breaks	a single number giving the number of cells for the histogram. Default is 50.
...	further arguments passed to or from other methods.

### Details

For the balance plot, a vertical line at threshold is used to define balance on covariates. The default value is threshold = 0.1 following Austin and Stuart (2015). If more than 2 treatments are considered, only density of the estimated generalized propensity scores will be produced, regardless of whether type = "density" or type = "hist".

### Value

Plot of the indicated type.

### References

Austin, P.C. and Stuart, E.A. (2015). Moving towards best practice when using inverse probability of treatment weighting (IPTW) using the propensity score to estimate causal treatment effects in observational studies. *Statistics in Medicine*, 34(28), 3661-3679.

### Examples

```

data("psdata")
ps.formula<-trt~cov1+cov2+cov3+cov4+cov5+cov6
msstat <- SumStat(ps.formula, trtgrp="2", data=subset(psdata, trt>1),
  weight=c("IPW", "overlap", "treated", "entropy", "matching"))

plot(msstat, type="hist")
plot(msstat, type="balance", weighted.var=TRUE, threshold=0.1, metric="ASD")

```

---

print.PStrim	<i>Print the results of PStrim</i>
--------------	------------------------------------

---

**Description**

The `print` method for class "PStrim"

**Usage**

```
## S3 method for class 'PStrim'  
print(x, ...)
```

**Arguments**

x	an object used to select a method.
...	further arguments passed to or from other methods.

**Value**

The output from `print`

---

print.PSweight	<i>Print the results of PSweight</i>
----------------	--------------------------------------

---

**Description**

The `print` method for class "PSweight"

**Usage**

```
## S3 method for class 'PSweight'  
print(x, ...)
```

**Arguments**

x	an object used to select a method.
...	further arguments passed to or from other methods.

**Value**

The output from `print`

---

print.PSweightsum	<i>Print the results of Summary.PSweight</i>
-------------------	--

---

**Description**

The `print` method for class "PSweightsum"

**Usage**

```
## S3 method for class 'PSweightsum'  
print(x, ...)
```

**Arguments**

x	an object used to select a method.
...	further arguments passed to or from other methods.

**Value**

The output from `print`

---

print.SumStat	<i>Print the results of SumStat</i>
---------------	-------------------------------------

---

**Description**

The `print` method for class "SumStat"

**Usage**

```
## S3 method for class 'SumStat'  
print(x, ...)
```

**Arguments**

x	an object used to select a method.
...	further arguments passed to or from other methods.

**Value**

The output from `print`

---

print.SumSumStat	<i>Print the results of Summary.SumStat</i>
------------------	---

---

**Description**

The `print` method for class "SumSumStat"

**Usage**

```
## S3 method for class 'SumSumStat'  
print(x, ...)
```

**Arguments**

x	an object used to select a method.
...	further arguments passed to or from other methods.

**Value**

The output from `print`

---

psdata	<i>Simulated dataset for PSweight</i>
--------	---------------------------------------

---

**Description**

This is a simulated observational study with three treatment groups to illustrate the utility of PSweight.

**Usage**

```
data(psdata)
```

**Format**

A data frame with 1500 rows and 8 columns.

**Details**

The simulated dataset includes 1500 rows, with each row representing information recorded from each individual. There are 8 variables (columns). The treatment is the variable `trt`, which has three treatment arms. The outcome of interest is variable `Y`. `cov1-cov6` are pre-treatment covariates among which `cov1-cov5` are continuous, and `cov6` is binary.

**Examples**

```
data("psdata")
```

PSmethod

*Fitting propensity score models with different methods***Description**

The function PSmethod is an internal function to estimate the propensity scores given a specified model through formula. It is built into function Sumstat, PStrim and PSweight.

**Usage**

```
PSmethod(
  ps.formula = ps.formula,
  method = "glm",
  data = data,
  ncate = ncate,
  ...
)
```

**Arguments**

ps.formula	an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the propensity score model to be fitted. Additional details of model specification are given under "Details". This argument is optional if ps.estimate is not NULL.
method	a character to specify the method for estimating propensity scores. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
data	an optional data frame containing the variables in the propensity score model.
ncate	a numeric to specify the number of treatment groups present in the given data.
...	further arguments passed to or from other methods.

**Details**

A typical form for ps.formula is `treatment ~ terms` where `treatment` is the treatment variable and `terms` is a series of terms which specifies a linear predictor. ps.formula by default specifies generalized linear models given the default argument `method = "glm"`. It fits the logistic regression when `ncate = 2`, and multinomial logistic regression when `ncate > 2`. The argument `method` allows user to choose model other than `glm` to fit the propensity score models. We have included `gbm` and `SuperLearner` as two alternative machine learning methods. Additional arguments of the machine learning estimators can be supplied through the `...` argument. Note that `SuperLearner` does not handle multiple groups and the current version of multinomial logistic regression is not supported by `gbm`. We suggest user to use them with extra caution. Please refer to the user manual of the `gbm` and `SuperLearner` packages for all the allowed arguments.

**Value**

`e.h` a data frame of estimated propensity scores.  
`beta.h` estimated coefficient of the propensity model when `method = "glm"`.

**Examples**

```
# the propensity model
ps.formula <- trt~cov1+cov2+cov3+cov4+cov5+cov6
psfit <- PSmethod(ps.formula = ps.formula,data = psdata,ncate=3)
```

PStrim

*Trim the input data and propensity estimate***Description**

Trim the original data and propensity estimate according to symmetric propensity score trimming rules.

**Usage**

```
PStrim(
  data,
  ps.formula = NULL,
  zname = NULL,
  ps.estimate = NULL,
  delta = 0,
  optimal = FALSE,
  out.estimate = NULL,
  method = "glm",
  ps.control = list()
)
```

**Arguments**

<code>data</code>	an optional data frame containing the variables required by <code>ps.formula</code> .
<code>ps.formula</code>	an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the propensity score model to be fitted. Additional details of model specification are given under "Details". This argument is optional if <code>ps.estimate</code> is not <code>NULL</code> .
<code>zname</code>	an optional character specifying the name of the treatment variable in <code>data</code> . Unless <code>ps.formula</code> is specified, <code>zname</code> is required.
<code>ps.estimate</code>	an optional matrix or data frame containing estimated (generalized) propensity scores for each observation. Typically, this is an N by J matrix, where N is the number of observations and J is the total number of treatment levels. Preferably, the column name of this matrix should match the name of treatment level, if column name is missing or there is a mismatch, the column names would be assigned according to alphabetic order of the treatment levels. A vector of propensity score estimates is also allowed in <code>ps.estimate</code> , in which case a binary treatment is implied and the input is regarded as the propensity to receive

	the last category of treatment by alphabetic order, unless otherwise stated by <code>trtgrp</code> .
<code>delta</code>	trimming threshold for estimated (generalized) propensity scores. Should be no larger than $1 / \text{number of treatment groups}$ . Default is 0, corresponding to no trimming.
<code>optimal</code>	an logical argument indicating if optimal trimming should be used. Default is FALSE.
<code>out.estimate</code>	an optional matrix or data frame containing estimated potential outcomes for each observation. Typically, this is an N by J matrix, where N is the number of observations and J is the total number of treatment levels. Preferably, the column name of this matrix should match the name of treatment level, if column name is missing or there is a mismatch, the column names would be assigned according to alphabetic order of the treatment levels, with a similar mechanism as in <code>ps.estimate</code> .
<code>method</code>	a character to specify the method for estimating propensity scores. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
<code>ps.control</code>	a list to specify additional options when method is set to "gbm" or "SuperLearner".

## Details

A typical form for `ps.formula` is `treatment ~ terms` where `treatment` is the treatment variable (identical to the variable name used to specify `zname`) and `terms` is a series of terms which specifies a linear predictor for treatment. `ps.formula` specifies a model for estimating the propensity scores, when `ps.estimate` is NULL. "glm" is the default method for propensity score estimation. Logistic regression will be used for binary outcomes, and multinomial logistic regression will be used for outcomes with more than two categories. The alternative method option of "gbm" serves as an API to call the `gbm()` function from the `gbm` package. Additional argument in the `gbm()` function can be supplied through the `ps.control=list()` argument in `SumStat()`. Please refer to the user manual of the "gbm" package for all the allowed arguments. Currently, models for binary or multinomial treatment will be automatically chosen based on the number of treatment categories. "SuperLearner" is also allowed in the `method` argument to call the `SuperLearner()` function in SuperLearner package. Currently, the SuperLearner method only support binary treatment with the default method set to "SL.glm". The estimation approach is default to "method.NNLS". Prediction algorithm and other tuning parameters can also be passed through `ps.control=list()`. Please refer to the user manual of the SuperLearner package for all the allowed specifications.

When comparing two treatments, `ps.estimate` can either be a vector or a two-column matrix of estimated propensity scores. If a vector is supplied, it is assumed to be the propensity scores to receive the treatment, and the treatment group corresponds to the last group in the alphabetic order, unless otherwise specified by `trtgrp`. When comparing multiple ( $J \geq 3$ ) treatments, `ps.estimate` needs to be specified as an N by J matrix, where N indicates the number of observations, and J indicates the total number of treatments. This matrix specifies the estimated generalized propensity scores to receive each of the J treatments. The same mechanism applies to `out.estimate`, except that the input for `out.estimate` must be an N by J matrix, where each row corresponds to the estimated potential outcomes (corresponding to each treatment) for each observation.

With binary treatments, `delta` defines the symmetric propensity score trimming rule following Crump et al. (2009). With multiple treatments, `delta` defines the symmetric multinomial trimming rule introduced in Yoshida et al. (2019). With binary treatments and when `optimal` equals TRUE,

the trimming function implements the optimal symmetric trimming rule in Crump et al. (2009). The optimal trimming threshold `delta` is then returned. With multiple treatments and `optimal` equals `TRUE`, the trimming function implements the optimal trimming rule in Yang et al. (2016). The optimal cutoff `lambda`, which defines the acceptable upper bound for the sum of inverse generalized propensity scores, is returned. See Yang et al. (2016) and Li and Li (2019) for details.

The argument `zname` is required when `ps.estimate` is not `NULL`.

## Value

PStrim returns a list of the following values:

`data` a data frame of trimmed data.

`trim_sum` a table summarizing the number of cases by treatment groups before and after trimming.

`ps.estimate` a data frame of propensity estimate after trimming.

`delta` an optional output of trimming threshold for symmetric trimming.

`lambda` an optional output trimming threshold for optimal trimming with multiple treatment groups.

`out.estimate` a data frame of estimated potential outcomes after trimming.

## Examples

```
data("psdata")

# the propensity model
ps.formula<-trt~cov1+cov2+cov3+cov4+cov5+cov6

# trim the original data by setting the threshold of propensity as 0.05
PStrim(data=psdata, ps.formula=ps.formula, delta=0.05)
PStrim(data=psdata, ps.formula=ps.formula, optimal=TRUE)
```

---

 PSweight

---

*Estimate average causal effects by propensity score weighting*

---

### Description

The function `PSweight` is used to estimate the average potential outcomes corresponding to each treatment group among the target population. The function currently implements the following types of weights: the inverse probability of treatment weights (IPW: target population is the combined population), average treatment effect among the treated weights (treated: target population is the population receiving a specified treatment), overlap weights (overlap: target population is the overlap population at clinical equipoise), matching weights (matching: target population is population obtained under 1:1 matching), entropy weights (entropy: target population is the population weighted by the entropy function). Augmented propensity score weighting estimators are also allowed, with propensity scores and outcome model estimates either estimated within the function, or supplied by external routines.

### Usage

```
PSweight(
  ps.formula = NULL,
  ps.estimate = NULL,
  trtgrp = NULL,
  zname = NULL,
  yname,
  data,
  weight = "overlap",
  delta = 0,
  augmentation = FALSE,
  bootstrap = FALSE,
  R = 50,
  out.formula = NULL,
  out.estimate = NULL,
  family = "gaussian",
  ps.method = "glm",
  ps.control = list(),
  out.method = "glm",
  out.control = list()
)
```

### Arguments

- |                          |  |
|--------------------------|--|
| <code>ps.formula</code>  | an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the propensity score model to be fitted. Additional details of model specification are given under "Details". This argument is optional if <code>ps.estimate</code> is not <code>NULL</code> . |
| <code>ps.estimate</code> | an optional matrix or data frame containing estimated (generalized) propensity scores for each observation. Typically, this is an N by J matrix, where N is the  |

number of observations and J is the total number of treatment levels. Preferably, the column name of this matrix should match the name of treatment level, if column name is missing or there is a mismatch, the column names would be assigned according to alphabetic order of the treatment levels. A vector of propensity score estimates is also allowed in `ps.estimate`, in which case a binary treatment is implied and the input is regarded as the propensity to receive the last category of treatment by alphabetic order, unless otherwise stated by `trtgrp`.

<code>trtgrp</code>	an optional character defining the "treated" population for estimating the average treatment effect among the treated (ATT). Only necessary if <code>weight = "treated"</code> . This option can also be used to specify the treatment (in a two-treatment setting) when a vector argument is supplied for <code>ps.estimate</code> . Default value is the last group in the alphabetic order.
<code>zname</code>	an optional character specifying the name of the treatment variable in data.
<code>yname</code>	an optional character specifying the name of the outcome variable in data.
<code>data</code>	an optional data frame containing the variables in the propensity score model and outcome model (if augmented estimator is used). If not found in data, the variables are taken from <code>environment(formula)</code> .
<code>weight</code>	a character or vector of characters including the types of weights to be used. "IPW" specifies the inverse probability of treatment weights for estimating the average treatment effect among the combined population. "treated" specifies the weights for estimating the average treatment effect among the treated. "overlap" specifies the (generalized) overlap weights for estimating the average treatment effect among the overlap population, or population at clinical equipoise. "matching" specifies the matching weights for estimating the average treatment effect among the matched population (ATM). "entropy" specifies the entropy weights for the average treatment effect of entropy weighted population (ATEN). Default is "overlap".
<code>delta</code>	trimming threshold for estimated (generalized) propensity scores. Should be no larger than $1 / \text{number of treatment groups}$ . Default is 0, corresponding to no trimming.
<code>augmentation</code>	logical. Indicate whether augmented weighting estimators should be used. Default is FALSE.
<code>bootstrap</code>	logical. Indicate whether bootstrap is used to estimate the standard error of the point estimates. Default is FALSE.
<code>R</code>	an optional integer indicating number of bootstrap replicates. Default is <code>R = 50</code> .
<code>out.formula</code>	an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the outcome model to be fitted. Additional details of model specification are given under "Details". This argument is optional if <code>out.estimate</code> is not NULL.
<code>out.estimate</code>	an optional matrix or data frame containing estimated potential outcomes for each observation. Typically, this is an N by J matrix, where N is the number of observations and J is the total number of treatment levels. Preferably, the column name of this matrix should match the name of treatment level, if column name is missing or there is a mismatch, the column names would be assigned

	according to alphabetic order of the treatment levels, with a similar mechanism as in <code>ps.estimate</code> .
<code>family</code>	a description of the error distribution and link function to be used in the outcome model. Only required if <code>out.formula</code> is provided. Supported distributional families include "gaussian" (link = identity), "binomial" (link = logit) and "poisson" (link = log). See <a href="#">family</a> in <code>glm</code> for more details. Default is "gaussian".
<code>ps.method</code>	a character to specify the method for estimating propensity scores. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
<code>ps.control</code>	a list to specify additional options when method is set to "gbm" or "SuperLearner".
<code>out.method</code>	a character to specify the method for estimating the outcome regression model. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
<code>out.control</code>	a list to specify additional options when <code>out.method</code> is set to "gbm" or "SuperLearner".

## Details

A typical form for `ps.formula` is `treatment ~ terms` where `treatment` is the treatment variable (identical to the variable name used to specify `zname`) and `terms` is a series of terms which specifies a linear predictor for treatment. Similarly, a typical form for `out.formula` is `outcome ~ terms` where `outcome` is the outcome variable (identical to the variable name used to specify `yname`) and `terms` is a series of terms which specifies a linear predictor for outcome. Both `ps.formula` and `out.formula` by default specify generalized linear models when `ps.estimate` and/or `out.estimate` is NULL. The argument `ps.method` and `out.method` allow user to choose model other than `glm` to fit the propensity score and outcome regression models for augmentation. Additional argument in the `gbm()` function can be supplied through the `ps.control` and `out.control` argument. Please refer to the user manual of the `gbm` package for all the allowed arguments. "SuperLearner" is also allowed in the `ps.method` and `out.method` arguments. Currently, the SuperLearner method only supports binary treatment with the default method set to "SL.glm". The estimation approach is default to "method.NNLS" for both propensity and outcome regression models. Prediction algorithm and other tuning parameters can also be passed through `ps.control` and `out.control`. Please refer to the user manual of the SuperLearner package for all the allowed specifications.

When comparing two treatments, `ps.estimate` can either be a vector or a two-column matrix of estimated propensity scores. If a vector is supplied, it is assumed to be the propensity scores to receive the treatment, and the treatment group corresponds to the last group in the alphabetic order, unless otherwise specified by `trtgrp`. When comparing multiple ( $J \geq 3$ ) treatments, `ps.estimate` needs to be specified as an  $N$  by  $J$  matrix, where  $N$  indicates the number of observations, and  $J$  indicates the total number of treatments. This matrix specifies the estimated generalized propensity scores to receive each of the  $J$  treatments. In general, `ps.estimate` should have column names that indicate the level of the treatment variable, which should match the levels given in `Z`. If column names are empty or there is a mismatch, the column names will be created following the alphabetic order of values in `Z`, and the rightmost column of `ps.estimate` is assumed to be the treatment group, when estimating ATT. `trtgrp` can also be used to specify the treatment group for estimating ATT. The same mechanism applies to `out.estimate`, except that the input for `out.estimate` must be an  $N$  by  $J$  matrix, where each row corresponds to the estimated potential outcomes (corresponding to each treatment) for each observation.

The argument `zname` and/or `yname` is required when `ps.estimate` and/or `out.estimate` is not NULL.

Current version of `PSweight` allows for five types of propensity score weights used to estimate ATE (IPW), ATT (treated) and ATO (overlap), ATM (matching) and ATEN (entropy). These weights are members of larger class of balancing weights defined in Li, Morgan, and Zaslavsky (2018). Specific definitions of these weights are provided in Li, Morgan, and Zaslavsky (2018), Li and Greene (2013), Zhou, Matsouaka and Thomas (2020). When there is a practical violation of the positivity assumption, `delta` defines the symmetric propensity score trimming rule following Crump et al. (2009). With multiple treatments, `delta` defines the multinomial trimming rule introduced in Yoshida et al. (2019). The overlap weights can also be considered as a data-driven continuous trimming strategy without specifying trimming rules, see Li, Thomas and Li (2019). Additional details on balancing weights and generalized overlap weights for multiple treatment groups are provided in Li and Li (2019).

If `augmentation = TRUE`, an augmented weighting estimator will be implemented. For binary treatments, the augmented weighting estimator is presented in Mao, Li and Greene (2018). For multiple treatments, the augmented weighting estimator is mentioned in Li and Li (2019), and additional details will appear in our ongoing work (Zhou et al. 2020+). When `weight = "IPW"`, the augmented estimator is also referred to as a doubly-robust (DR) estimator.

When `bootstrap = TRUE`, the variance will be calculated by nonparametric bootstrap, with `R` bootstrap replications. The default of `R` is 50. Otherwise, the variance will be calculated using the sandwich variance formula obtained in the M-estimation framework.

## Value

`PSweight` returns a `PSweight` object containing a list of the following values: estimated propensity scores, average potential outcomes corresponding to each treatment, variance-covariance matrix of the point estimates, the label for each treatment group, and estimates in each bootstrap replicate if `bootstrap = TRUE`. A summary of `PSweight` can be obtained with `summary.PSweight`.

`trtgrp` a character indicating the treatment group.

`propensity` a data frame of estimated propensity scores.

`muhat` average potential outcomes by treatment groups, with reference to specific target populations.

`covmu` variance-covariance matrix of `muhat`.

`muboot` an optional list of point estimates in each bootstrap replicate `bootstrap = TRUE`.

`group` a table of treatment group labels corresponding to the output point estimates `muhat`.

```

---

summary.PSweight	<i>Summarize a PSweight object</i>
------------------	------------------------------------

---

## Description

summary.PSweight is used to summarize the results from [PSweight](#). The output contains the average causal effects defined by specific contrasts, as well as their standard error estimates.

## Usage

```
## S3 method for class 'PSweight'
summary(object, contrast = NULL, type = "DIF", CI = TRUE, ...)
```

## Arguments

object            a PSweight object obtained from the [PSweight](#) function.

contrast	a vector or matrix specifying the causal contrast of interest. The average causal effects will be defined by such contrasts. For multiple treatments, the contrast parameters are explained in Li and Li (2019) for estimating general causal effects. Default is all pairwise contrasts between any two treatment groups.
type	a character specifying the target estimand. The most commonly seen additive estimand is specified by <code>type = "DIF"</code> , abbreviated for weighted difference-in-means. This is the usual pairwise average treatment effects as those defined in Li, Morgan, and Zaslavsky (2018) and Li and Li (2019). For binary (or count outcomes), we also allow two ratio estimands: causal relative risk ( <code>type = "RR"</code> ) and causal odds ratio ( <code>type = "OR"</code> ). Estimates for these two ratio estimands will be reported on the log scale (log relative risk and log odds ratio) to improve the approximate for asymptotic normality. With binary outcomes, "DIF" is the same as the average causal risk difference. Default is "DIF" if left empty.
CI	a logical argument indicates whether confidence interval should be calculated. Default is <code>CI = TRUE</code> .
...	further arguments passed to or from other methods.

## Details

For the `contrast` argument, one specifies the contrast of interest and thus defines the target estimand for comparing treatments. For example, if there are three treatment levels: A, B, and C, the contrast A-C (i.e.,  $E[Y(A)] - E[Y(C)]$ ) can be specified by `c(1, 0, -1)`. The contrasts of A-C and B-C can be jointly specified by `rbind(c(1, 0, -1), c(0, 1, -1))`.

For estimating the causal relative risk (`type = "RR"`), the contrast is specified at the log scale. For example, the contrast A-C (specified by `c(1, 0, -1)`) implies the estimation of  $\log\{E[Y(A)]\} - \log\{E[Y(C)]\}$ . For estimating the causal odds ratio, the contrast is specified at the log odds scale. For example, the contrast A-C (specified by `c(1, 0, -1)`) implies the estimation of  $\log\{E[Y(A)]/E[1-Y(A)]\} - \log\{E[Y(C)]/E[1-Y(C)]\}$ .

The variance of the contrasts will be estimated by the delta method (if `sandwich` variance is used, or `bootstrap = FALSE`), or nonparametric bootstrap (if `bootstrap = TRUE`). Details will be given in Zhou et al. (2020+).

The argument `type` takes one of three options: "DIF", "RR", or "OR", with "DIF" as the default option. Typically, "RR" is relevant for binary or count outcomes, and "OR" is relevant only for binary outcomes. "DIF" applies to all types of outcomes.

## Value

A list of following values:

- `estimates` a matrix of point estimates, standard errors, test statistics, 95 for contrasts of interest.
- `bootestimates` a list of data frames containing estimated contrasts in each bootstrap replicate, if `bootstrap` is used to estimate standard errors.
- `contrast` a table listing the specified contrasts of interest.
- `group` a table of treatment group labels corresponding to the output point estimates, provided in results obtained from [PSweight](#).
- `trtgrp` a character indicating the treatment group, or target population under ATT weights.

type a character specifying the target estimand.

CI a logical indicator of whether confidence interval should be reported.

## Examples

```
## For examples, run: example(PSweight).
```

---

summary.SumStat	<i>Summarize a SumStat object.</i>
-----------------	------------------------------------

---

## Description

summary.SumStat is used to summarize results obtained from function [SumStat](#). The output includes effective sample sizes and tables for balance statistics.

## Usage

```
## S3 method for class 'SumStat'
summary(object, weighted.var = TRUE, metric = "ASD", ...)
```

## Arguments

object	a SumStat object obtained with the <a href="#">SumStat</a> function.
weighted.var	logical. Indicate whether the propensity score weighted variance should be used in calculating the balance metrics. Default is TRUE.
metric	a character indicating the type of balance metrics. "ASD" refers to the pairwise absolute standardized difference and "PSD" refers to the population standardized difference. Default is "ASD".
...	further arguments passed to or from other methods.

## Details

For metric, the two options "ASD" and "PSD" are defined in Li and Li (2019) for the general family of balancing weights. Similar definitions are also given in McCaffrey et al. (2013) for inverse probability weighting. weighted.var specifies whether weighted or unweighted variance should be used in calculating ASD or PSD. An example of weighted variance with two treatment groups is given in Austin and Stuart (2015). For more than two treatment groups, the maximum of ASD (across all pairs of treatments) and maximum of PSD (across all treatments) are calculated, as explained in Li and Li (2019).

**Value**

A list of tables containing effective sample sizes and balance statistics on covariates for specified propensity score weighting schemes.

`effective.sample.size` a table of effective sample sizes. This serves as a conservative measure to characterize the variance inflation or precision loss due to weighting, see Li and Li (2019).

`unweighted` A table summarizing mean, variance by treatment groups, and standardized mean difference.

`IPW` If "IPW" is specified, this is a data table summarizing mean, variance by treatment groups, and standardized mean difference under inverse probability of treatment weighting.

`treated` If "treated" is specified, this is a data table summarizing mean, variance by treatment groups, and standardized mean difference under the ATT weights.

`overlap` If "overlap" is specified, this is a data table summarizing mean, variance by treatment groups, and standardized mean difference under the (generalized) overlap weights.

`matching` If "matching" is specified, this is a data table summarizing mean, variance by treatment groups, and standardized mean difference under the (generalized) matching weights.

`entropy` If "entropy" is specified, this is a data table summarizing mean, variance by treatment groups, and standardized mean difference under the (generalized) entropy weights.

**Examples**

```
## For examples, run: example(SumStat).
```

SumStat

*Calculate summary statistics for propensity score weighting***Description**

SumStat is used to generate distributional plots of the estimated propensity scores and balance diagnostics after propensity score weighting.

**Usage**

```
SumStat(
  ps.formula = NULL,
  ps.estimate = NULL,
  trtgrp = NULL,
  Z = NULL,
  covM = NULL,
  zname = NULL,
  xname = NULL,
  data = NULL,
  weight = "overlap",
  delta = 0,
  method = "glm",
  ps.control = list()
)
```

**Arguments**

- |             |   |
|-------------|---|
| ps.formula  | an object of class <code>formula</code> (or one that can be coerced to that class): a symbolic description of the propensity score model to be fitted. Additional details of model specification are given under "Details". This argument is optional if ps.estimate is not NULL.   |
| ps.estimate | an optional matrix or data frame containing estimated (generalized) propensity scores for each observation. Typically, this is an N by J matrix, where N is the number of observations and J is the total number of treatment levels. Preferably, the column names of this matrix should match the names of treatment level, if column names are missing or there is a mismatch, the column names would be assigned according to the alphabetic order of treatment levels. A vector of propensity score estimates is also allowed in ps.estimate, in which case a binary treatment is implied and the input is regarded as the propensity to receive the last category of treatment by alphabetic order, unless otherwise stated by trtgrp. |
| trtgrp      | an optional character defining the "treated" population for estimating the average treatment effect among the treated (ATT). Only necessary if weight = "treated". This option can also be used to specify the treatment (in a two-treatment setting) when a vector argument is supplied for ps.estimate. Default value is the last group in the alphabetic order.  |

<code>Z</code>	an optional vector specifying the values of treatment, only necessary when the covariate matrix <code>covM</code> is provided instead of data.
<code>covM</code>	an optional covariate matrix or data frame including covariates, their interactions and higher-order terms. When the covariate matrix <code>covM</code> is provided, the balance statistics are generated according to each column of this matrix.
<code>zname</code>	an optional character specifying the name of the treatment variable in data.
<code>xname</code>	an optional vector of characters including the names of covariates in data.
<code>data</code>	an optional data frame containing the variables in the propensity score model. If not found in data, the variables are taken from <code>environment(formula)</code> .
<code>weight</code>	a character or vector of characters including the types of weights to be used. "IPW" specifies the inverse probability weights for estimating the average treatment effect among the combined population (ATE). "treated" specifies the weights for estimating the average treatment effect among the treated (ATT). "overlap" specifies the (generalized) overlap weights for estimating the average treatment effect among the overlap population (ATO), or population at clinical equipoise. "matching" specifies the matching weights for estimating the average treatment effect among the matched population (ATM). "entropy" specifies the entropy weights for the average treatment effect of entropy weighted population (ATEN). Default is "overlap".
<code>delta</code>	trimming threshold for estimated (generalized) propensity scores. Should be no larger than 1 / number of treatment groups. Default is 0, corresponding to no trimming.
<code>method</code>	a character to specify the method for estimating propensity scores. "glm" is default, and "gbm" and "SuperLearner" are also allowed.
<code>ps.control</code>	a list to specify additional options when method is set to "gbm" or "SuperLearner".

## Details

A typical form for `ps.formula` is `treatment ~ terms` where `treatment` is the treatment variable (identical to the variable name used to specify `zname`) and `terms` is a series of terms which specifies a linear predictor for treatment. `ps.formula` specifies logistic or multinomial logistic models for estimating the propensity scores, when `ps.estimate` is NULL.

When comparing two treatments, `ps.estimate` can either be a vector or a two-column matrix of estimated propensity scores. If a vector is supplied, it is assumed to be the propensity scores to receive the treatment, and the treatment group corresponds to the last group in the alphabetic order, unless otherwise specified by `trtgrp`. When comparing multiple ( $J \geq 3$ ) treatments, `ps.estimate` needs to be specified as an  $N$  by  $J$  matrix, where  $N$  indicates the number of observations, and  $J$  indicates the total number of treatments. This matrix specifies the estimated generalized propensity scores to receive each of the  $J$  treatments. In general, `ps.estimate` should have column names that indicate the level of the treatment variable, which should match the levels given in `Z`. If column names are empty or there is a mismatch, the column names will be created following the alphabetic order of treatment levels. The rightmost column of `ps.estimate` is then assumed to be the treatment group when estimating ATT ("treated"). `trtgrp` can also be used to specify the treatment group for estimating ATT.

To generate balance statistics, one can directly specify `Z` and `covM` to indicate the treatment levels and covariate matrix. Alternatively, one can supply `data`, `zname`, and `xname` to indicate the same

information. When both are specified, the function will prioritize inputs from `Z` and `covM`. When `ps.estimate` is not `NULL`, argument `zname`.

Current version of `PSweight` allows for five types of propensity score weights used to estimate ATE ("IPW"), ATT ("treated"), and ATO("overlap"), ATM "matching" and ATEN "entropy". These weights are members of a larger class of balancing weights defined in Li, Morgan, and Zaslavsky (2018). When there is a practical violation of the positivity assumption, `delta` defines the symmetric propensity score trimming rule following Crump et al. (2009). With multiple treatments, `delta` defines the multinomial trimming rule introduced in Yoshida et al. (2019). The overlap weights can also be considered as a data-driven continuous trimming strategy without specifying trimming rules, see Li, Thomas and Li (2019). Additional details on balancing weights and generalized overlap weights for multiple treatment groups are provided in Li and Li (2019). For details about matching weights and entropy weights, please refer to Li and Greene (2013) and Zhou, Matsouaka and Thomas (2020).

"glm" is the default method for propensity score estimation. Logistic regression will be used for binary outcomes, and multinomial logistic regression will be used for outcomes with more than two categories. The alternative method option of "gbm" serves as an API to call the `gbm()` function from the `gbm` package. Additional argument in the `gbm()` function can be supplied through the `ps.control=list()` argument in `SumStat()`. Please refer to the user manual of the `gbm` package for all the allowed arguments. Currently, models for binary or multinomial treatment will be automatically chosen based on the number of treatment categories. "SuperLearner" is also allowed in the method argument to pass the propensity score estimation to the `SuperLearner()` function in `SuperLearner` package. Currently, the `SuperLearner` method only supports binary treatment with the default method set to "SL.glm". The estimation approach is default to "method.NNLS" in the `SumStat()` function. Prediction algorithm and other tuning parameters can also be passed through `ps.control=list()` to `SumStat()`. Please refer to the user manual of the `SuperLearner` package for all the allowed specifications.

## Value

`SumStat` returns a `SumStat` object including a list of the following value: treatment group, propensity scores, propensity score weights, effective sample sizes, and balance statistics. A summary of `SumStat` can be obtained with `summary.SumStat`.

`trtgrp` a character indicating the treatment group.

`propensity` a data frame of estimated propensity scores.

`ps.weights` a data frame of propensity score weights.

`ess` a table of effective sample sizes. This serves as a conservative measure to characterize the variance inflation or precision loss due to weighting, see Li and Li (2019).

`unweighted.sumstat` A list of tables including covariate means and variances by treatment group and standardized mean differences.

`ATE.sumstat` If "IPW" is included in `weight`, this is a list of summary statistics using inverse probability weighting.

`ATT.sumstat` If "treated" is included in `weight`, this is a list of summary statistics using the ATT weights.

`ATO.sumstat` If "overlap" is included in `weight`, this is a list of summary statistics using the overlap weights.

ATM.sumstat If "matching" is included in weight, this is a list of summary statistics using the matching weights.

ATEN.sumstat If "entropy" is included in weight, this is a list of summary statistics using the entropy weights.

trim If  $\delta > 0$ , this is a table summarizing the number of observations before and after trimming.
